*Abstract-* Several important fish populations within the fish community of the St. Marys River exhibited increases in abundance in 2006. Improved recruitment since 2003 seemed to drive increases for walleye, yellow perch, and smallmouth bass. Northern pike have declined and there is concern that this species may be impacted by continuing low water levels. Cisco abundance remained low relative to past surveys. Total annual mortality rates remained unchanged for most species but increased for smallmouth bass and was high for yellow perch in some reaches of the river. Walleye diet showed a shift away from alewives which is consistent with the decline of alewife abundance in most of Lake Huron. Special concerns for the fish community in the river include the continuing trends of lower cisco abundance, the status of specific spawning stocks of walleye within the river, the presence of the exotic white perch and what impact it may have in the future, the potential for the exotics Eurasian ruffe, round goby, and rusty crayfish to reach and invade the fish community. Information needs for the future are: a) more frequent fish community assessments; b) better indices of recruitment for most species; c) contribution of hatchery walleye to the river population. Other needs for the river include the development of fish community objectives to better facilitate management and to allow a context with which to better interpret the findings of the fish community survey.

## Introduction

The St. Marys River hosts a diverse fish community, many species of which provide for valuable sport, commercial, and tribal subsistence fisheries. The sport fishery alone is substantial and has been estimated to have consisted of as much as one third of the total open water sport fishing pressure for all US waters of Lake Huron in 1999 (Fielder et al. 2002), and was estimated to have generated up to \$11 million US dollars in Michigan and Ontario from 1999 to 2000 for the open water and ice fishery combined (Fielder et al. 2002).

Despite the strong sport fishery, the river fish community is challenged by a number of threatening issues including the effects of sea lamprey and potential for establishment of other invasive species, predation effects of large numbers of cormorants (*Phalacrocorax auritus*), and diminishing habitat due to low water levels in the upper Great Lakes and water resource issues. There are also management issues including concern about the sustainability of these fisheries in the river, the need for common sport fishing regulations for Ontario and Michigan waters, and questions about the impact stocked walleye may have on the sustainability of wild walleye in the river. These issues highlight the need for a comprehensive fishery management plan or establishment of fish community objectives for the St. Marys River to permit issue resolution and coordinated efforts to benefit the fishery. At minimum, these issues highlight the value of assessment information to document and possibly track the effects of stressors and fish community changes.

Fishery issues are complicated by the diversity of fishery interests on the river (Fielder 2002). Local, state, federal, international, and tribal resource managers have fishery management interests in the river and a number of stakeholders groups value the fishery for their livelihood and enjoyment. In 1997 the St. Marys River Fishery Task Group (SMRFTG) was formed by the Great Lakes Fishery Commission's Lake Huron Committee. It included representatives from all major resource agencies with the goal of designing a fishery assessment and review program for the St. Marys River that would address the needs of all agencies (Fielder 2002). A river fishery assessment plan was developed in 2002 that included the need for and outlined a protocol for a fish community assessment for the St. Marys River (Gebhardt et al. 2002). The protocol followed a Michigan DNR (MDNR) assessment program that was initiated in 1975 and was repeated every four to eight years.

The objectives of this survey are to assess and provide information on the abundance, growth, mortality and size structure of important fish populations found in the St. Marys River; to make comparisons to previous surveys; and to comment on the overall current status of certain notable species.

## Study Site

The St. Marys River is a connecting channel between Lakes Superior and Huron (Figure 1). The river flows southeasterly about 112 km and empties into Lake Huron at De Tour, Michigan but also drains into Ontario's North Channel through the St. Joseph Channel and Potagannissing Bay. Three large islands divide the river flow into these various channels and the river is bordered on the northeast by Ontario and Michigan on the other side. The river includes a variety of lacustrine reaches; specifically Lake Nicolet, Lake George, Lake Munuscong, and Raber Bay. For practical purposes, and for this study, Potagannissing Bay is also considered part of the St. Marys River. The rapids at Sault Ste. Marie is perhaps one of the most well known features of this river, although today 93% of the river flow is diverted for hydroelectric generation (Edsall and Gannon 1993). The St. Marys River aquatic habitat includes an expanse of coastal wetlands that provide spawning and

nursery habitat for fish. Duffy et al. (1987) describes in detail the ecological and physical characteristics of the St. Marys River.

## Methods

This study followed the fish community assessment procedure recommended by Gebhardt et al. (2002) which in turn was based on the methods used by past surveys (Schorfhaar 1975; Miller 1981; Grimm 1989; Fielder and Waybrant 1998; Fielder et al. 2003) so as to allow comparability. Multifilament nylon gillnets were used to collect fish in this study. In this survey and in 2002 the nets measured 1.8 m deep by 304.8 m long and were comprised of ten different mesh sizes. Each mesh was in a 30.5 m long panel. Mesh sizes were; 38.1mm, 50.8 mm, 63.5 mm, 76.2 mm, 88.9 mm, 101.6 mm, 114.3 mm, 127.0 mm, 139.7 mm, and 152.4 mm stretch measure. The survey nets in 1975, 1979, 1987, and 1995 only 4 mesh sizes were utilized: 50.8 mm, 63.5 mm, 76.2 mm and 114.3 mm stretch measure mesh and panels were 30.5 m in length. Nets were fished overnight on the bottom for all surveys.

Field work was jointly conducted by the member agencies of the St. Marys River Fisheries Task Group. They were the Bay Mills Indian Community (BMIC), Chippewa Ottawa Resource Authority (CORA), Michigan Department of Natural Resources (MDNR), Ontario Ministry of Natural Resources (OMNR), Fisheries and Oceans Canada (DFO), and the United States Fish and Wildlife Service (USFWS). Net set locations were divided throughout the St. Marys River (Figure 1). Sites number 6 and 17 were not sampled in 2006 due to local conditions. For the purpose of some analyses, data was organized by seven different distinct areas (Table 1).

The catch from each lift was identified, weighed (round weight) and measured for total length. Scales or dorsal spines were collected for aging from walleye (see appendix 1 for a complete listing of all the common and scientific names of fishes mentioned in this report), yellow perch, smallmouth bass, northern pike, all salmonines, and cisco. These same species were internally inspected for sex, maturity (according to the methods of Fielder 1998), stomach contents, and for salmonids; visceral fat index scoring (according to the methods of Goede 1989). Stomach contents were identified when possible and enumerated. Stomach contents of certain species of interest are reported as incidence (percent void and percent with contents) and proportion of occurrence which is the percent of that prey item in the total of all prey items consumed by that species.

Catch-per-unit-of-effort (CPUE) was expressed two ways; first, the total number of each species per net lift or number per 304.8 m of net across all mesh sizes was determined while the second was to express CPUE based only on the catch collected from the same mesh sizes used in past surveys (prior to 2002). This second method of expressing CPUE allowed a more direct comparison for trend purposes and was standardized (extrapolated when necessary) to 304.8 m of net length. In 2006, 8 net sets from Potagannissing Bay were excluded from this expression of CPUE due to a lack of separation in the data by mesh size. The CPUE values of the two different methods are also contrasted to explore comparability.

Total annual mortality was derived using the Robson-Chapman method (Van Den Avyle and Hayward 1999) on certain species of interest. Age information was also organized by CPUE so as to compare year class strength. Growth rate was expressed as mean length-at-capture-at-age and compared to Michigan averages according to Schneider et al. (2000) and to Lake Huron averages for those species. The Lake Huron data were means of total length from the North Channel of Lake Huron for collections made in similar times of the year (OMNR unpublished data). Survey growth rate averages were also compared to data from past surveys. Condition was expressed as relative

weight (Wr; Ney 1999). Growth parameters were further explored via length / weight relationships and Von Bertalanffy growth equations (Van Den Avyle and Hayward 1999) for some species.

Statistical analyses included comparison of means via the nonparametric Kruskal-Wallis (K-W) test. Testing for differences of means between two independent samples used the t-test where possible and the Mann-Whitney U (M-WU) test when the assumption of normality could not be met. Nonparametric procedures were used because gillnet CPUE data were rarely normally distributed. Comparison of the mean CPUE values between the expanded mesh nets (full compliment of mesh sizes fished) and the traditional mesh panels alone (used by past surveys) were standardized to a uniform total net length of 304.8 m to ensure comparability. Some data and means from past surveys were recalculated for reporting and comparison purposes in this report and may differ slightly from those reported by past authors. Length / weight analysis used log transformed data for linear regressions. All statistical tests were performed at the significance level of  $P=0.05$  and followed the methods of Sokal and Rohlf (1981). Analysis was performed with the aid of SPSS computer software (SPSS 2001).

## Results

A total of 3,841 specimens were collected in the survey, representing 31 different species. The mean CPUE of walleye in 2006 was the greatest measured since 1975 (Table 2) and the mean CPUE was significantly different among the survey years (K-W test;  $P=0.001$ ). Yellow perch mean CPUE increased in 2006 and the various survey year means were also significantly different (K-W test;  $P=0.006$ ). The difference, however, appears to stem from the higher mean CPUE exhibited in 1987 compared to the other years which were otherwise similar. Northern pike mean CPUE continued to decline to its lowest measured level in 2006, and there was a significant difference among surveyed years (K-W test;  $P<0.001$ ). Similarly, there was a significant difference in mean CPUE of smallmouth bass which showed an increase among surveyed years (K-W test;  $P<0.001$ ), and the 2006 mean CPUE value was significantly greater than the 2002 value and represented a new high for the survey series (M-WU test;  $P=0.011$ ) (Table 2). Cisco mean CPUE in 2006 was very low compared to past surveys, but mean CPUE among years was not significantly different (K-W test;  $P=0.066$ ). A record high mean CPUE for rock bass was also observed in 2006. The exotic white perch, first collected in 2002, was again collected in 2006 but at a lower abundance (Table 2).

As stated in the methods the gillnet specifications used in the 2002 and 2006 surveys differed from past survey years in that additional meshes were added. The CPUEs summarized in Table 2 were standardized to only include the catch from those mesh sizes in common with all survey years to allow comparison. It remains possible that some of the available catch was spread over more mesh sizes in the two recent surveys, thereby lowering the CPUE value of the traditional meshes alone. If so, the mean CPUE of the full mesh complement fished in 2002 and 2006 would be greater than that of the traditional meshes alone. This was again explored in 2006 by comparing the mean CPUE of each species between the expanded mesh net (full complement of mesh sizes fished; 10) and the traditional mesh sizes (4 panels) (Table 3). Under this comparison, the mean CPUE of cisco was not significantly different (M-WU test;  $P=0.457$ ) in 2006, though it was in 2002. Mean CPUE was again significantly greater for northern pike in the traditional mesh (M-WU test;  $P=0.026$ ), consistent with the findings in 2002. The CPUE from the expanded mesh catch was also slightly lower for walleye and smallmouth bass but not significantly different in either 2006 or 2002. The yellow perch catch was essentially the same in the comparison for 2006 (M-WU test;  $P=0.612$ ) as it had been in 2002 (Table 3).

The St. Marys River encompasses a large variety of habitats. Some indication can be derived of where changes in abundance have occurred by examining trends in CPUE by river reach. Northern pike exhibited a substantial decline in CPUE within Lake George in 2006 compared to past survey years, although the CPUE was not significantly different from 2002 (M-WU test;  $P=0.301$ ). Northern pike CPUE also dropped in Potagannissing Bay (Table 4). Cisco became abundant again in Raber Bay in 2006, a location where they were abundant early in the survey series. Cisco have continued to decline in Potagannissing Bay but their absence in 2006 may stem partly from the omission of most of those net sets in 2006 from the traditional CPUE expressions (as catches were not separated by mesh size). Increases in smallmouth bass were driven mainly by gains in Lake Munuscong and the St. Joseph Channel reaches of the St. Marys River. The record river-wide mean CPUE of walleye was driven by gains in all reaches of the river, though the most substantial increases were observed in the Upper River, Lake George, and Potagannissing Bay reaches. Yellow perch mean CPUE also increased in all reaches except the St. Joseph Channel and Potagannissing Bay.

Patterns of abundance across age and year classes indicate some among-species trends. Percids (walleye and yellow perch) exhibited strong year classes since 2003 (ages 1-3), and yellow perch had a good year class in 2002, as well (age 4) (Tables 5 and 6 respectively). Such patterns of increased recruitment were not evident for cisco (Table 7) and northern pike (Table 8). Smallmouth bass, like the Percids, also appeared to exhibit stable recruitment since 2003 (Table 9).

Trends in total annual mortality varied by species. Yellow perch total annual mortality rate increased in three reaches of the St. Marys River, but was largely unchanged from 2002 on a river wide basis (Table 10). The increase in recruitment in recent years violates the assumption of equal annual recruitment for this method of mortality estimation and may account for some of these increases, including in Potagannissing Bay. Total annual mortality rate for other species was largely unchanged except for smallmouth bass, where the total annual mortality rate appears to be increasing (Table 10). Generally, all the total annual mortality rates were largely within sustainable levels; however, the yellow perch river-wide rate, as well as some reach-specific rates, are high and consistent with heavy exploitation.

Walleye growth rate, as indicted by mean length at age, remained largely unchanged since 2002 (Table 5) but still reflects a general trend of improved growth rate since the survey series began in the mid-1970s. The mean length is a reflection of the younger mean age, which in turn likely stems from the increased recruitment in recent years. Growth rate of yellow perch increased in all reaches of the river in 2006 except for the St. Joseph Channel (Table 6). Like walleye, there has been a trend towards improved growth over the survey series. Cisco growth rate has remained largely unchanged and cisco generally grow faster than the Michigan state average, but not as fast as the average for cisco in the Ontario waters of the rest of Lake Huron (Table 7). Northern pike exhibited an improved growth rate in 2006 across all ages (Table 8). Smallmouth bass continue to grow slower than the Michigan state average rate for length at age, but better than the Ontario Lake Huron average rate (Table 9). The 2006 rate, however, is an improvement over past years of the survey series.

Approximately half of female yellow perch were sexually mature by the time they were 18 cm in total length. This corresponds to the minimum length limit imposed by Michigan for the sport fishery (Table 11). Females were fully mature at about 21 cm total length. Female smallmouth bass are achieving 100% maturity by 30 cm, well in advance of the 36 cm Michigan minimum length limit. Maturity of female northern pike did not follow a consistent threshold (Table 11), possibly a result of low sample size. The 61 cm Michigan minimum length limit appears to be within the range of maturity for pike. Ontario presently maintains no length limits in the St. Marys River

except on walleye in the Lake George vicinity where a 46 cm maximum length limit is in place. Michigan maintains a 38 cm minimum length limit on the same species. It appears that female walleye in the St. Marys River consistently achieve 100% maturity around 51 cm total length.

The diet of walleye, at the time of the survey, has exhibited a shift away from alewife in 2002 to one dominated by rainbow smelt in 2006 (Table 12). Walleye were the only species, of those examined, still showing any utilization of alewives in the St. Marys River, and this phenomena is likely a reflection of the lake-wide decline of alewives in the rest of Lake Huron. Crayfish figured prominently in the diet of all other species examined, but not walleye (Table 12). The most varied diet was that of northern pike which made similar usage of a number of fish species as prey. Condition, as indicated by relative weight, was largely unchanged for most species, but there may be some indication of a declining trend in walleye (Table 13). Walleye condition was lowest in the upper river reach of the St. Marys. Smallmouth bass continue to exhibit a high condition level in the St. Marys River.

Incidence of sea lamprey wounding was greatest for chinook salmon (Table 14). No sea lamprey wounds were observed on lake whitefish in 2006, but 5.9% of the lake whitefish captured in 2002 exhibited wounds. Generally, proportions of fish showing sea lamprey wounds declined in 2006 except for cisco and Chinook salmon. The most common wound class exhibited was A3 (should this be A1?) and B1 (see King and Edsall 1979 for classification explanation). White sucker exhibited the largest range of wound classification, but this may have been an artifact of their relatively large sample size.

Walleye stocking in the St. Marys River has continued by CORA and the Michigan DNR since the last survey (Table 15). The greatest plants are in the upper river reach and Potagannissing Bay. Length/weight regression equations and Von Bertalanffy growth equations for five notable species are presented in Appendix 2. Length frequency distributions for these species from the survey catch are presented in Appendix 3.

## **Discussion**

### *Walleye*

Walleye were the fourth most abundant species (as measured by CPUE) in the St. Marys River during the 2006 survey, behind yellow perch, white suckers, and rock bass (Table 2). Walleye CPUE (11.18) in 2006 was the highest measured over the survey series (1975-2006). Catch for this species had been remarkably stable over previous surveys, with CPUE values ranging from 3.58 in 2002 to the previous high of 7.47 in 1987 (Table 2). Angler reports of exceptional walleye fishing confirm the increased abundance observed during this survey.

Although CPUE increased throughout the river, the increase was especially pronounced in the Upper River, Lake George and Potagannissing Bay. Fielder et al. (2002) hypothesized that increased abundance in the Upper River may be due to stocking efforts in Waishkey Bay, while increases in abundance in Lake George may be due to walleye length limits in both Ontario and Michigan waters, the only reach in the survey to have dual regulations. Although incongruent in combination (OMNR is a maximum length limit and MDNR is a minimum length limit), the two acting in concert may be limiting the harvest and building the population. These regulations may also protect walleye which undertake seasonal migrations into Lake George following spawning in Lake Munuscong (Liston et al 1986).

Hatchery composition of walleye year classes in the Upper River also indicate that stocking may have contributed to the higher CPUE. Since all walleye stocked in the St. Marys are marked with oxytetracycline (OTC), the ratio of OTC- marked fish to unmarked fish shows the relative contribution of stocked fish. Analysis shows that 85.6% of the age-0 walleye captured in the Upper River during annual fall walleye surveys (1998-2006, N=90) were of hatchery origin (SMRFTG, unpublished data).

In addition to the dual regulations, increases in walleye abundance in Lake George may also be the result of walleye stocking on the south side of that reach. A total of 68,951 spring fingerling walleye were stocked in Lake George in 2004-2006. A limited dataset (2004 and 2006, N=52) show 28.8% of the age-0 walleye captured during fall electrofishing surveys in Lake George were of hatchery origin (SMRFTG, unpublished data).

Walleye CPUE in Munuscong Bay (4.2) was the highest observed in the survey series, despite elevated water temperatures in this shallow bay. Angler reports during the survey indicated that more walleye were in the deeper, colder waters of the shipping channel. Catch rates may have been higher if nets had been set in the shipping channel, but shipping traffic precluded that option. Munuscong River and Bay provide important walleye spawning and nursery habitat, so have not been stocked in recent years. There is concern that stocking walleye on top of healthy wild populations may be detrimental.

Age-1 to Age-3 walleye had the highest CPUE during this survey, corresponding to the 2003-2005 year classes with walleye up to age-14 captured. The 2003 year class was especially strong for percid natural reproduction in other parts of the Great Lakes as well (Fielder et al. In Press, Fielder and Thomas 2006, Thomas and Haas 2007). Walleye were not stocked in the St. Marys River in 2005, indicating that natural reproduction likely plays a strong role in year class strength. Relative contributions of natural reproduction and stocking to the St. Marys River walleye population should become evident as data on recruitment trends are collected through annual fall walleye evaluations.

The St. Marys River Fisheries Task Group has initiated an annual fall walleye electrofishing survey to evaluate year class strength throughout the St. Marys River and complement data collected during the periodic fish community surveys. While some member agencies had been doing similar work since 1992, the coordinated, river-wide fall surveys began in 2004. The 2004 year-class had the highest CPUE in the fall electrofishing surveys since 2002, which also corresponded as the strongest year class in the 2006 gill net survey. The mean CPUE for age-0 walleye in 2003 and 2005, however, was lower than the average since 1992 (SMRFTG, unpublished data). The walleye recruitment study is described in the St. Marys River Walleye Stocking and Evaluation Plan.

Mean CPUE of walleyes in the St. Marys River fish community survey in 2006 was 11.18, after reaching a low for the survey series in 2002 at 3.58. Walleye CPUE in Saginaw Bay using similar gear averaged 6.6 to 13.0 from 1998-2004 (Fielder and Thomas 2006). Saginaw Bay is a shallow, productive bay of Lake Huron that is well known for its walleye fishery, and has seen strong year classes of wild walleye since 2003. Although the St. Marys River is much less productive, the 2006 walleye catch rate in the St. Marys River put it well in the range of CPUE values seen in Saginaw Bay.

Total annual mortality (38%) for walleye was slightly lower in 2006 compared to the 2002 (49%) and 1995 (51%) values (Table 10). Losses and extractions of walleye from the St. Marys River are primarily due to angling and predation. Angler harvest in the walleye fishery can be as much as

25,000 (Fielder et al. 2002). Based on a creel survey done from 1999-2000, walleye are the second most sought after species in the St. Marys River sport fishery (Fielder et al. 2002).

Mean length-at-age for walleye in the 2006 survey was slightly above the state of Michigan average. The growth index, which compares length-at-age to state average, was +9 mm. The 2002 survey was the only other in the survey series that showed an above average growth index for this species in the St. Marys River. The above average growth indicates that walleye are growing very well, considering that the river originates from cold Lake Superior outflow. Compared to mean-lengths-at-age for walleye from the North Channel in 2006 (OMNR, unpublished data), however, St. Marys River walleye had a growth index of -35 mm (Table 5).

Rainbow smelt were the most common prey item (46% occurrence) for walleye based on the examination of stomach contents of fish captured during the survey. This is a shift from the walleye diet found in 2002, in which alewife were more abundant in the diet, with rainbow smelt occurring much less frequently. The switch in walleye diet from alewife to smelt may be reflective of a lake-wide decline in alewife abundance in Lake Huron (Bence and Mohr In Press). Smelt were also more prominent than alewife in walleye diet during the 1995 survey (Fielder and Waybrant 1998), although they were not as prevalent as in the present survey. Other identifiable items in walleye stomachs in 2006 were mayflies, cisco, ninespine stickleback, and white sucker. Gizzard shad, which were a component of walleye diets in previous surveys, were also absent from walleye stomachs in 2006.

Mean condition (87) as measured by relative weight was slightly lower in 2006 than 2002. Highest relative weights were found in Lake Nicolet and Lake George, while the lowest relative weights were found in Raber Bay. The lower condition value may be a result of the increased abundance of walleye observed in the 2006 survey; that is, more fish competing for food resources. The above average growth index, however, indicates that the fish are still growing well and that there is not a shortage of prey.

#### *Northern Pike*

Northern pike gillnet CPUE continued its overall decline since the 1987 survey (Table 2). However in an area by area comparison with the 2002 survey CPUE was very slightly improved or remained the same for all areas except Lake George and Potagannissing Bay which declined noticeably (Table 4). The coastal wetlands of this area of the river have been considerably affected by the low spring water levels of the past five years which may be having a negative effect on pike spawning success. Lake Munuscong CPUE (5) had improved from 2002 survey (0) but is still very low compared to past survey years. This area of the river is also shallow and ringed by a wetland fringe. Low water levels and the influence of lake effect seiches may impact spawning and nursery habitat in Lake Munuscong. Mortality has not changed appreciably since the 1995 survey (Table 10). Recruitment may be affected by the loss of habitat associated with current low water levels.

Age distribution has lessened since 2002 (Table 8) and age-1 made up 44% of the catch compared to 54% of the catch being composed of age-2 and 3 fish in 2002. The truncated age structure is consistent with continuing mortality in a declining recruitment situation. Growth for pike is up from 2002 and for the first time in the survey series consistent with the decline in abundance, the growth index was above the Michigan state average.

Northern pike diet continues to be predominantly fish (47%) with yellow perch being the most common in fish examined (Table 12). Other species included white sucker, ninespine stickleback and rainbow smelt. Crayfish (21.7%) were the only invertebrate noted. In this survey fewer fish

were unidentifiable which may account for the higher presence of perch observed compared to 2002. Northern pike condition improved in all areas of the river from the values for 2002 but are not appreciably different than 1995 survey consistent with improved growth. Maturity thresholds were not discernable in the fish captured due to the small sample size. Females at 34, 42 and 47 cm were visibly mature while others over 34 cm were not. As in 2002 no sea lamprey wounding was observed for northern pike.

### *Yellow Perch*

Perch abundance in the St. Marys River continues to be stable over the time series (Table 2) and perhaps trending upward since the last record high in 1987. Annual index gillnet surveys<sup>1</sup> in the adjacent North Channel of Lake Huron, (OMNR 2004, 2005, 2006), also showed a continued upward trend in abundance. Perch were most abundant in Lake George followed by Raber Bay and the Upper River. Potagannissing Bay had very low abundance which may be due in part to data deficiencies in the 2006 survey (Table 4). Alewives collapsed in Lake Huron in 2003 and improved reproductive success of percids has been credited to their absence (Fielder et al. In Press). Other phenomenon may have contributed to improved yellow perch recruitment including ideal climatic conditions in 2003 and the implementation of cormorant control in the Michigan waters of the area (BMIC, unpublished data). The age structure of the catch is consistent with stronger 2003 and 2004 year classes (Table 6). Abundance in the St. Joseph Channel area was much less than in the 2002 survey when it had the highest CPUE. However, with only two data points, four years apart, the significance of this abrupt change is not clear. The St. Joseph Channel supports a popular winter perch fishery and a short duration but significant early spring angling effort occurs when perch move into shallows to spawn (OMNR unpublished data). Over all, perch abundance in each area has improved from the 1995 and 2002 surveys (St. Joseph Channel and Potagannissing Bay areas excluded).

Total annual mortality for the entire river increased slightly from 2002 and continues to trend upward for the recent time series (1995-2006). Mortality was highest in Potagannissing Bay, Lake Munuscong and the Upper River. Potagannissing Bay and Lake Munuscong receive high annual harvests of perch (Fielder et al. 2002, SMRFTG unpublished data). Cormorant predation may also influence mortality due to the close proximity to rookeries.

Consistent with the stronger yellow perch year classes since 2003 in the St. Marys River, the areas of the North Channel and southern Georgian Bay reflect similar age structures suggesting a regional effect. This may reflect improved reproductive success again stemming from the collapse of alewives. In contrast, yellow perch populations in the Ontario waters of southern Lake Huron were more heavily dominated by older ages (OMNR 2006).

In 2006 most age-3 fish met Michigan's angling minimum perch size limit of 178 mm. The upper river (only Michigan waters surveyed) was the only area where the mean length at age suggested that some age-2 fish were legal angling size. In 2002 most age-3 fish barely met the minimum size limit. Only about half the female yellow perch were achieving maturity by 178 mm (Table 11).

Growth rate (mean length at age) continued the increasing trend from 1995 for age-4 and younger fish river wide. When compared to the Michigan state average the yellow perch growth index was higher than reported in 2002 (Table 6) and generally better than the Michigan state average but

---

<sup>1</sup> OMNR index series gear uses monofilament nets which make direct comparison of CPUE between projects open to interpretation. Reporting of trends is still useful.

more in line with the Ontario average mean length-at-age for the North Channel. On the whole, yellow perch growth rate is improving over the time series since 1975.

Perch diet has not changed from the 2002 survey in items and relative occurrence. Crayfish continue to be an important prey item (60%) followed by fish (31%). Fish species included Johnny darter, slimy sculpin and ninespine stickleback, however, most of the fish items were unidentifiable (Table 12). Casual observations suggested fewer crayfish encountered in collection gear in 2006. Sea lamprey predation on yellow perch continues to be negligible with less than 0.5% wounding for 1,627 fish examined.

### *Smallmouth Bass*

Overall the smallmouth bass population in the St. Marys River appears healthy. Although the data collected during this survey seem to conflict at times, the population seems to be increasing despite an increase in total annual mortality.

There was a significant increase in mean CPUE of smallmouth bass in 2006 (K-W test;  $P < 0.001$ ). The 2006 mean CPUE value represents a new high for the survey (Table 2). This increase was driven entirely by the Lake Munuscong and St. Joseph Channel reaches which had mean CPUE values 2 to 3 times greater than the remaining reaches. Bass abundance in both these reaches was significantly higher than those recorded in the 2002 survey (Table 4). The central portion of the river seems to remain good habitat for smallmouth bass. The increase in river-wide mean CPUE of smallmouth bass is interesting since the total annual mortality rate has increased from 0.36 and 0.37 in 1995 and 2002 respectively to 0.55 in 2006 (Table 10). In addition, with an increase in mean CPUE, growth rates have also increased, which like the increase in mortality rate, seems contrary to expected population dynamics which typically show as populations increase, mortality is low and growth decreases. The data collected indicates just the opposite. This could be a result of a population that is still far below carrying capacity or a result of small sample size. The condition factor for 2006 is high and although the mean length-at-age increased substantially from 2002 to 2006 the mean is still well below the state average but more in line with the Ontario average for North Channel populations. This supports the idea that the population is still below carrying capacity and that density dependent factors have not yet been expressed (Tables 9 & 13).

As the 2002 survey showed, smallmouth bass continue to rely on fish and crayfish as their primary prey items. Yellow perch was the top fish eaten followed by slimy sculpin, ninespine stickleback and white sucker (Table 12). In all, smallmouth bass diet in the St. Mary's River remains relatively simple depending heavily on crayfish and a few prey fish species.

### *Cisco*

Overall cisco populations have trended lower in the river although their distribution makes quantitative assessment during the time of year the survey is conducted difficult to fully assess. Growth rates and mortality rates generally indicate the population is still relatively healthy.

Cisco mean CPUE in 2006 increased over the record low 2002 survey but still remains low compared to past surveys (Table 2). A significant increase was observed in the Raber Bay reach of the river which dominated the catch (Table 4). This is one location where they were abundant early in the survey series. Cisco have continued to decline in Potagannissing Bay but their lack in 2006 may stem partly from the omission of most of those net sets in 2006 from the traditional CPUE expressions (from a lack of mesh-specific data).

Cisco growth rate has trended slower over the time series but is generally in line with the Michigan state average and the Ontario average for the North Channel (Table 7).

### *Special Concerns*

In 2002, questions arose as to whether cisco abundance was actually lower than previous surveys or if ciscoes were displaying patchy distribution due to thermal preferences and availability of prey resources. Given the depressed stock levels in Lake Huron and the potential for the St. Marys River to be a source of recovery stocks, this population should be monitored closely to determine if stocks have declined or if survey methods are not adequately sampling the population during this time period. A new recreational creel limit of 25 (12 fish conservation limit) cisco was implemented by Ontario in 2008 to address concerns of excessive possession.

The 2002 report expressed concerns regarding the spawning runs of walleye in the St. Marys River, which have long been supplemented with plantings of hatchery fish. In 2006, the CPUE for walleye was the greatest measured since 1975 (Table 2). Yellow perch and smallmouth bass also increased in 2006; however, northern pike were at their lowest CPUE since the beginning of the surveys. Better information is needed to determine the relationship between the abundance of walleye and the capacity of the river to either sustain or increase the walleye population. The relationship of walleye to other potential competitors, including smallmouth bass and northern pike, is also important in the management of the species. The completion of the St. Marys River Walleye Stocking and Evaluation Plan provides a study design to evaluate the walleye population in the river, both natural and stocked, and would provide a starting point for examining the relationship of walleye to other species in the river.

White perch, an aquatic invasive from the Atlantic Ocean, were again collected in 2006, though at abundance levels lower than in 2002. In 2002 and 2006, collections were made in Munuscong and Raber Bays, and in 2006 three white perch were also collected in Potagannissing Bay at stations 39 and 42 (Figure 1). Thus, while the abundance was lower in 2006, the distribution of white perch has expanded in the river. Given that this species has been documented to consume walleye eggs (Schaeffer and Margraf 1987), continued monitoring of their distribution is warranted. Other potential invaders include both the Eurasian ruffe and the round goby. In 2006 ruffe were documented in Tahquamenon River, 55 km west of the Sault Locks (Czypinski et al. 2006), and round goby have been collected in the North Channel on Manitoulin Island. It is expected that these species will eventually reach the St. Marys River given the close proximity of both species to the river. Rusty crayfish were first documented at the mouth of the Munuscong River in 2007 (D. Traynor, LSSU, Personal Communication). The potential impact of these or new species, either alone or in combination, on the river ecosystem is unknown and as such further monitoring both their spread and impact on arrival will be critical.

Although cormorant management has begun in the area (BMIC, unpublished data), the role of this species should continue to be considered and managed so as to benefit fish populations and strive for a sustainable level of cormorants. Cooperative efforts among management agencies should be coordinated and a river wide strategy developed.

Continuing trends of declining water levels in the river due to decreased outflows from Lake Superior and Lake Huron levels poses a potential issue for species dependent on coastal wetlands and seasonally flooded areas for spawning or nursery habitat. Management of water levels in the Great Lakes and connecting channels needs to consider environmental and fishery needs in addition to commercial interests.

### *Information Needs*

Continued monitoring of the fish community in the St. Marys River remains essential. The frequency should be increased in accordance with the original St. Marys River Fishery Assessment Plan (Gebhardt et al. 2002). More information is needed on reproductive success and recruitment of all species. The addition of a trawling or electrofishing survey would be greatly beneficial to our understanding of the fish community within the river. The recently begun study of walleye recruitment will be a valuable element to this end. The current creel survey operated jointly between the MDNR and OMNR has been fragmented and is proving difficult to extract the needed information. Better funding and more complete coverage of the river is needed. The overall management of the St. Marys River fishery resources would greatly benefit from the development of river-wide joint fish community objectives. These objectives would allow the development of management strategies and a better context with which to interpret findings from the Fish Community Index Surveys. The development of common recreational fishing regulations between Ontario and Michigan remains a need. Development of fish community objectives will drive this effort in addition to the continued assessment of the dynamics of the fish community.

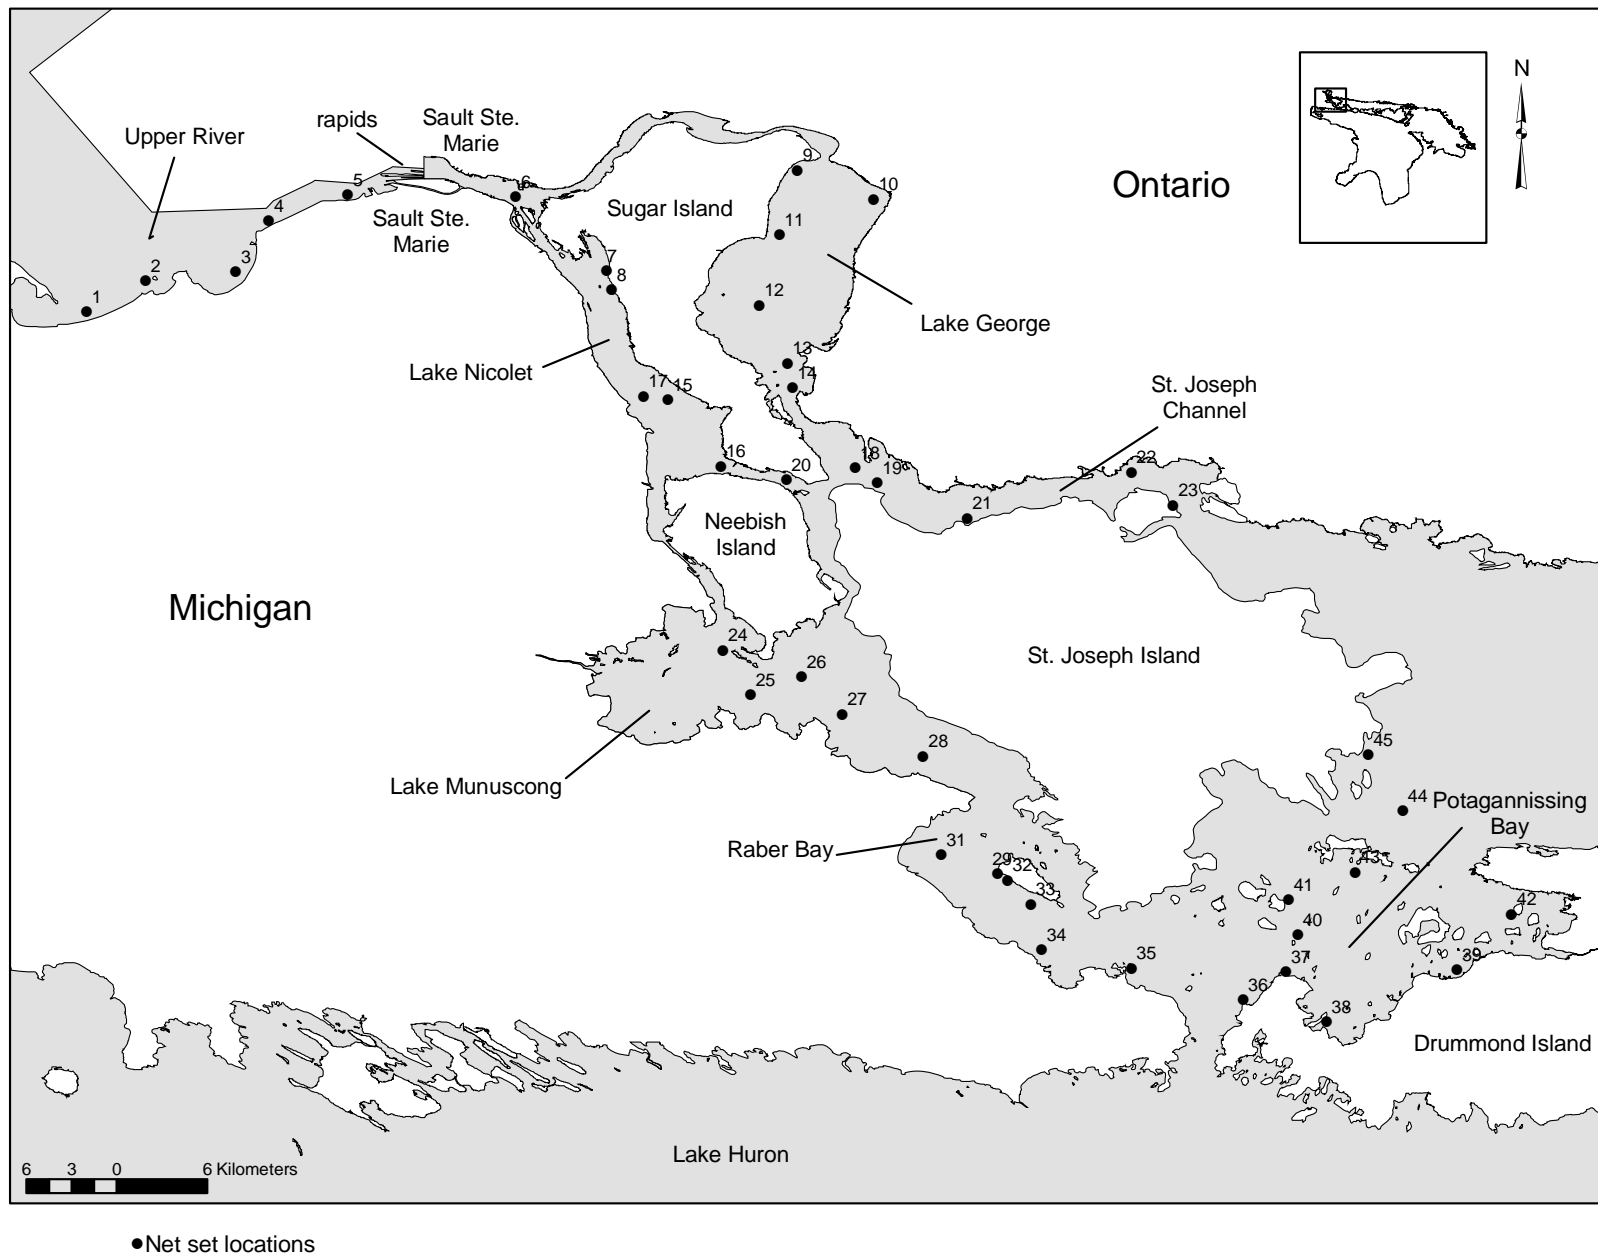

Figure 1. St. Marys River and location of gillnet sets made in August 2006. Not sampled were site numbers 6 & 17.

Table 1. Net set locations used to define areas within the St. Marys River for the purpose of certain data analyses, along with a list of the agencies that performed the field work. See Figure 1 for location of each net number.

Area	Net set numbers	Agency
Upper River	1, 2, 3, 4, 5	BMIC
Lake Nicolet	6, 7, 8, 15, 16, 17, 20	USFWS
Lake George	9, 10, 11, 12, 13, 14	CORA, OMNR & DFO
Lake Munuscong	24, 25, 26, 27, 28	MDNR
St. Joseph Channel	18, 19, 21, 22, 23	OMNR & DFO
Raber Bay	31, 32, 33, 34, 35	CORA & BMIC
Potagannissing Bay	36, 37, 38, 39, 40, 41, 42, 43, 44, 45	MDNR, OMNR & DFO

Table 2. Mean Catch-Per-Unit-of-Effort (CPUE) of all species collected from the St. Marys River 1975 through 2006. Means are based on number per 304.8 m (1000 ft) of gillnet with standard error in parentheses. Total nets set were 32 each in 1975 and 1979, 27<sup>b</sup> in 1987, 51<sup>c</sup> in 1995, 44 in 2002, and 42 in 2006, although only 34 sets are represented here due to data recording limitations. The St. Joseph Channel portion of the St. Marys was added to the survey series beginning in 2002.

<sup>a</sup> See Appendix 1 for a complete list of common and scientific names of fishes mentioned in this report.

<sup>b</sup> Mean CPUEs for 1987 are calculated from a restored data set that lacked five net sets compared to those summarized in Grimm 1987.

<sup>c</sup> Mean CPUEs for 1995 included the influence of 3.81 cm (1.5 inch) mesh net on some sets performed in the Raber and Potagannissing area of the river. This effort was incorporated in to the calculation of CPUE but may still have slightly inflated mean CPUE for certain species such as yellow perch and alewife.

Table 3. Mean Catch-Per-Unit-of-Effort (CPUE) of all species collected from the St. Marys River in 2002 and 2006 with all ten mesh sizes included (Expanded mesh) and from the traditional mesh (4 mesh sizes). Means are based number per 304.8 m (1000 ft) of gillnet with standard error in parentheses. There were 44 total nets set in 2002 and 42 in 2006. The traditional mesh CPUE values in 2006 reflect a sample size of 34 net sets.

Species <sup>a</sup>	2002		2006	
	Expanded mesh	Traditional mesh	Expanded mesh	Traditional mesh
Alewife	10.61 (7.84)	0.11 (0.11)	1.12 (0.73)	0.00 (0.00)

<sup>a</sup> Means from these areas included some efforts of 3.51 c, (1.5 in.) mesh. While compensated for in the calculation of CPUE, the influence of the smaller mesh may have slightly inflated the mean for certain species such as yellow perch.

<sup>b</sup> Potagannissing Bay mean CPUE values for 2006 reflect only two net sets via the traditional mesh sizes and was probably under-sampled for the purpose of this reach specific analysis.

Table 5. Catch-per-unit-of-effort (CPUE) of walleye by age and mean length-at-age at capture for the St. Marys River, August-September, 2006. For comparison, mean length-at-age is included from past surveys and the Michigan state average length-at-age<sup>1</sup> as well as the Ontario Lake Huron 2006 North Channel (ON NC) average<sup>2</sup>. Unit of effort is one 304.8 m gillnet set. Growth index<sup>1</sup> compares length-at-age to state average and the 2006 year to the NC average. It excludes age groups represented by less than 5 specimens. All lengths and the growth index are in mm. CPUE values by age may omit some un-aged fish and therefore may not total to the overall CPUE for this species as reported in Table 2.

Table 7. Catch-per-unit-of-effort (CPUE) of cisco by age and mean length-at-age at capture for the St. Marys River, August - September, 2006. For comparison, mean length-at-age is included from past surveys and the Michigan state average length-at-age<sup>1</sup> as well as the Ontario Lake Huron 2006 North Channel (ON NC) average<sup>2</sup>. Unit of effort is one 304.8 m gillnet set. Growth index<sup>1</sup> compares length-at-age to state average and the 2006 year to the NC average. It excludes age groups represented by less than 5 specimens. All lengths and the growth index are in mm. CPUE values by age may omit some un-aged fish and therefore may not total to the overall CPUE for this species as reported in Table 2.

Appendix 1. Common and scientific names of fishes and other aquatic organisms mentioned in this report.

Common name	Scientific name
Alewife	<i>Alosa pseudoharengus</i>
Atlantic salmon	<i>Salmo salar</i>
Black crappie	<i>Pomoxis nigromaculatus</i>
Bloater	<i>Coregonus hoyi</i>
Bowfin	<i>Amia calva</i>
Brook trout	<i>Salvelinus fontinalis</i>
Brown bullhead	<i>Ictalurus nebulosus</i>
Brown trout	<i>Salmo trutta</i>
Burbot	<i>Lota lota</i>
Channel catfish	<i>Ictalurus punctatus</i>
Chinook salmon	<i>Oncorhynchus tshawytscha</i>
Cisco (cisco)	<i>Coregonus artedii</i>
Coho salmon	<i>Oncorhynchus kisutch</i>
Common carp	<i>Cyprinus carpio</i>
Eurasian ruffe	<i>Gymnophthalmus cernuus</i>
Freshwater drum	<i>Aplodinotus grunniens</i>
Gizzard shad	<i>Dorosoma cepedianum</i>
Johnny darter	<i>Etheostoma nigrum</i>
Lake trout	<i>Salvelinus namaycush</i>
Lake whitefish	<i>Coregonus clupeaformis</i>
Longnose gar	<i>Lepisosteus osseus</i>
Longnose sucker	<i>Catostomus catostomus</i>
Menominee	<i>Prosopium cylindraceum</i>
Northern hogsucker	<i>Hypentelium nigricans</i>
Northern pike	<i>Esox lucius</i>
Pink salmon	<i>Oncorhynchus gorbuscha</i>
Rainbow smelt	<i>Osmerus mordax</i>
Rainbow trout	<i>Oncorhynchus mykiss</i>
Rock bass	<i>Ambloplites rupestris</i>
Round goby	<i>Neogobius melanostomus</i>
Sculpin	<i>Cottus bairdi</i>
Sea lamprey	<i>Petromyzon marinus</i>
Smallmouth bass	<i>Micropterus dolomieu</i>
Splake	<i>S. fontinalis x S. namaycush</i>
Tiger musky	<i>Esox masquinongy</i>
Trout-perch	<i>Percopsis omiscomaycus</i>
Walleye	<i>Sander vitreus</i>
White bass	<i>Morone chrysops</i>
White perch	<i>Morone americana</i>
White sucker	<i>Catostomus commersoni</i>
Yellow perch	<i>Perca flavescens</i>

Appendix 2. Length-weight regression equations and von Bertalanffy growth equations for select species from the St. Marys River August – September 2006. Length/weight equation logs are base 10, weight (wt) is in grams, and length (len) is in mm. Von Bertalanffy equations are based on mean length-at-age data where ‘t’ is age in years.

Species	Length/Weight Equation	Len/Wt $r^2$	Von Bertalanffy Equation	K	$L_\infty$	$t_0$
Walleye	$\log(\text{wt})=3.230 \log(\text{len})-5.648$	0.96	$L_t=547[1-e^{-0.3432(t-0.57)}]$	0.3432	547	0.57
Yellow perch	$\log(\text{wt})=3.251 \log(\text{len})-5.480$	0.95	$L_t=311[1-e^{-0.2654(t+1.39)}]$	0.2654	311	-1.39
Smallmouth bass	$\log(\text{wt})=3.077 \log(\text{len})-5.004$	0.96	$L_t=417[1-e^{-0.5038(t+1.31)}]$	0.5038	417	-1.31
Northern pike	$\log(\text{wt})=2.941 \log(\text{len})-5.091$	0.85	$L_t=731[1-e^{-0.4089(t+1.15)}]$	0.4089	731	-1.15
Cisco	$\log(\text{wt})=3.267 \log(\text{len})-5.703$	0.95	$L_t=451[1-e^{-0.2158(t+1.99)}]$	0.2158	451	-1.99

Appendix 3. Length frequencies from survey catch of; (a) walleye, (b) yellow perch, (c) smallmouth bass, (d) northern pike, and (e) cisco from the St. Marys River, August and September 2006 .

Appendix 3 continued.

Appendix 3 continued.
